Abstract. We present several applications of quantum amplitude amplification for deciding whether all elements in the image of a given function are distinct, for finding an intersection of two sorted tables, and for finding a triangle in a graph. Our techniques generalize and improve those of Brassard, Høyer, and Tapp [*ACM SIGACT News*, 28 (1997), pp. 14–19]. This shows that in the quantum world element distinctness is significantly easier than sorting, in contrast to the classical world.

Key words. quantum query complexity, element distinctness, collision problem

AMS subject classification. 68Q25

DOI. 10.1137/S0097539702402780

1. Introduction. In the last decade, quantum computing has become a prominent and promising area of theoretical computer science. Realizing this promise will require two things: actually building a quantum computer and discovering tasks where a quantum computer is significantly faster than a classical computer. Here we are concerned with the second issue. Few good quantum algorithms are known to date. The two main examples are Shor's algorithm for factoring [23], which achieves an exponential speed-up over the best known classical factoring algorithms, and Grover's search algorithm [15], which achieves a quadratic speed-up over classical search algorithms. Whereas the first so far has remained a seminal but somewhat isolated result, the second has been applied as a building block in quite a few other quantum algorithms [6, 8, 9, 10, 21, 20, 7, 12].

The security of the widely used cryptosystem RSA is based on the assumption that it is hard to factor integers. Shor's algorithm solves precisely this task. In the same vein, the security of digital signatures is based on the assumption that it is difficult to find two items that map to the same value for some particular function. This motivates the research on the quantum complexity of this task. We define different variants of this problem. Though we do not improve the bounds for the following problem, we define it first to start our explanation. We use $[N]$ to denote $\{1, \dots, N\}$.

COLLISION PROBLEM

input $f : [N] \rightarrow [M]$ which is 2-to-1, i.e., $\forall i \in [N] \exists! j \in [N], i \neq j : f(i) = f(j)$

output $i, j \in [N]$ with $i \neq j$ and $f(i) = f(j)$

complexity Classically, the bounded-error query complexity is $\Theta(N^{1/2})$. For a quantum computer the bounded-error query complexity is $\Theta(N^{1/3})$: In 1997 Brassard, Høyer, and Tapp [8] gave a bounded-error quantum algorithm using $O(N^{1/3})$ queries to f , and in 2002 Aaronson and Shi [1] showed the matching lower bound.

In the following problem we remove the assumption about the input. The birthday paradox gives a simple relation between both problems. A random subset of size \sqrt{N} of the domain of any 2-to-1 function contains with high probability a collision pair. Therefore any bounded-error algorithm for Element Distinctness using $O(N^\alpha)$ queries implies a bounded-error algorithm for the Collision Problem using $O(N^{\alpha/2})$ queries.

ELEMENT DISTINCTNESS

input $f : [N] \rightarrow [M]$

output $i, j \in [N]$ with $i \neq j$ and $f(i) = f(j)$, or “all distinct” if f is injective

complexity We present a bounded-error quantum algorithm which makes $O(N^{3/4})$ queries. It dates from early 2000 and first appeared in [11]. However, recently the bounded-error quantum query complexity was shown to be $\Theta(N^{2/3})$: The lower bound follows from Aaronson and Shi [1] by the observation above, and an algorithm matching this bound was found in 2003 by Ambainis [3] using a quantum walk. The classical bounded-error query complexity is $\Theta(N)$ by a trivial reduction from the OR-problem: For an OR-instance $x \in \{0, 1\}^N$ we define the function $f : [N + 1] \rightarrow [N + 1]$, where $f(N + 1) = 0$ and for all $i \in [N]$ $f(i) = (1 - x_i)i$. Now $\text{OR}(x) = 1$ if and only if f contains a collision pair.

The element distinctness problem has been well studied classically [24, 18, 14, 5]. It is particularly interesting because its classical complexity is related to that of sorting, which is well known to require $N \log N + \Theta(N)$ comparisons in the classical world. If we sort f , we can decide element distinctness by going through the sorted list once, which gives a classical upper bound of $N \log N + O(N)$ comparisons. Conversely, element distinctness requires $\Omega(N \log N)$ comparisons in the case of classical bounded-error algorithms (even in a much stronger model [14]), so sorting and element distinctness are essentially equally hard classically. On a quantum computer, the best known upper bound for sorting is $0.53 N \log N$ comparisons [13], and such a linear speed-up is best possible: quantum sorting requires $\Omega(N \log N)$ comparisons, even if one allows a small probability of error [16]. Accordingly, our $O(N^{3/4} \log N)$ upper bound shows that element distinctness is significantly easier than sorting for a quantum computer, in contrast to the classical case.

In this paper we also give algorithms for related problems. Typically, web search engines like Google associate to every word a list of pages containing it (sorted in order of its page rank) and when the query is “Rolling Stones,” for example, then the search engine must output the intersection of the lists associated to the words “Rolling” and “Stones.” Now imagine a search engine implemented on a quantum computer. This motivates the following problem.

LIST INTERSECTION

input $f, g : [N] \rightarrow [M]$ each is monotone increasing

output $i, j \in [N]$ with $i \neq j$ and $f(i) = f(j)$, or “lists disjoint” if the images of f and g are disjoint

complexity We present a bounded-error quantum algorithm which makes $O(\sqrt{N}c^{\log^* N})$ queries to f for some constant $c > 1$. A trivial lower bound $\Omega(\sqrt{N})$ can be obtained by a reduction from the OR-problem: given an OR-instance $x \in \{0, 1\}^N$, define $f, g : [N] \rightarrow [2N + 1]$ by $f(i) = 2i + 1$ and $g(i) = 2i + x_i$ for all $i \in [N]$. Then f and g are ordered, and $\text{OR}(x) = 1$ iff the LIST INTERSECTION problem has a solution. The same reduction shows that the classical bounded-error query complexity is $\Theta(N)$.

The function $\log^*(N)$ is defined as the minimum number of iterated applications of the logarithm function necessary to obtain a number less than or equal to 1: $\log^*(N) = \min\{i \geq 0 \mid \log^{(i)}(N) \leq 1\}$, where $\log^{(i)} = \log \circ \log^{(i-1)}$ denotes the i th iterated application of \log , and $\log^{(0)}$ is the identity function. Even though $c^{\log^*(N)}$ is exponential in $\log^*(N)$, it is still very small in N , in particular $c^{\log^*(N)} \in o(\log^{(i)}(N))$ for any constant $i \geq 1$.

To a function $f : [N] \rightarrow [M]$ we can associate a *collision graph* $G(V, E)$ with $V = [N]$ and $(i, j) \in E$ if $i \neq j$ and $f(i) = f(j)$. The Element Distinctness problem simply consists of finding an edge in G . An interesting problem is to ask whether G contains some fixed subgraph. A simple, yet nontrivial subgraph is the triangle, i.e., the complete graph on three vertices.

TRIANGLE FINDING

input the symmetric adjacency matrix $M : [n] \times [n] \rightarrow \{0, 1\}$ of a graph with m edges

output $u, v, w \in [n]$ such that $M(u, v) = M(v, w) = M(w, u) = 1$, or “failure” if the graph contains no triangle

complexity We present a bounded-error quantum algorithm which needs $O(n + \sqrt{nm})$ queries. A better algorithm has been found in 2003, with $O(n^{1.3})$ bounded-error query quantum complexity [19], while Yao [25] showed a lower bound of $\Omega(n^{2/3} \log^{1/6} n)$. Classically a simple reduction from the OR-problem shows that the bounded-error query complexity is $\Theta(n^2)$, even if $m = O(n)$.

2. Preliminaries. We assume the reader is familiar with the formalism of quantum computing; otherwise we refer to [22]. The quantum ingredient of our algorithms is *amplitude amplification* [7], which generalizes quantum search [15]. The essence of amplitude amplification can be summarized by the following theorem.

THEOREM 2.1 (amplitude amplification). *There exists a quantum algorithm QSearch with the following property. Let \mathcal{A} be any quantum algorithm that uses no measurements and that maps $|0\rangle$ to a superposition $\sum_{x \in X} \alpha_x |x\rangle$ for some set X . Let $g : X \rightarrow \{0, 1\}$ be a function testing whether a basis state represents a solution or not. Let p be the success probability of \mathcal{A} , i.e., $p^2 = \sum_{x: g(x)=1} |\alpha_x|^2$. Let S_g be an operator implementing g such that $S_g |x\rangle = (-1)^{g(x)} |x\rangle$ for every $x \in X$. Then algorithm QSearch finds a solution using an expected number of $O(1/\sqrt{p})$ applications of \mathcal{A} , \mathcal{A}^{-1} , and S_g if $p > 0$, and otherwise runs forever.*

Note that when an algorithm \mathcal{A} does make measurements during its computation there is a standard trick that transforms it into an equivalent algorithm \mathcal{A}' that

does not. We replace every measurement with an operator writing the value, which would be the result of the measurement, in a new register, which initially is all zero. In the rest of the computation, every computation depending on the result of the measurement will depend rather on the content of this register.

QSearch works by iterating the unitary transformation $Q = -\mathcal{A}S_0\mathcal{A}^{-1}S_g$ a number of times, starting with initial state $\mathcal{A}|0\rangle$. The operator S_0 is defined as $S_0|0\rangle = -|0\rangle$ and $S_0|x\rangle = |x\rangle$ for all $x \neq 0$. The analysis of [7] shows that a measurement after $\Theta(1/\sqrt{p})$ iterations of Q yields a solution with probability close to 1. The algorithm QSearch does not need to know the value of p in advance, but if p is known, then a slight modification finds a solution *with certainty* using $O(1/\sqrt{p})$ applications of \mathcal{A} , \mathcal{A}^{-1} , and S_g .

Grover's algorithm for searching a space of N items is a special case of amplitude amplification, where \mathcal{A} is the Hadamard transform on each qubit. This \mathcal{A} has probability $p \geq 1/N$ of finding a solution (if there is at least one), so amplitude amplification implies an $O(\sqrt{N})$ quantum algorithm for searching the space. We refer to this process as "quantum searching."

3. Element distinctness.

ALGORITHM: FIND A COLLISION PAIR IN $f : [N] \rightarrow [M]$

1. Partition the domain of f into disjoint sets $S_1, \dots, S_{\sqrt{N}}$ of size $O(\sqrt{N})$ each.
2. Apply amplitude amplification to the following *inner block*:
 - (a) Select a random subset S_k of the partition.
 - (b) Query all values $f(i)$ for $i \in S_k$, and build a binary search tree over the set $f(S_k) := \{f(i) : i \in S_k\}$. If S_k contains a collision pair, output it.
 - (c) Otherwise search $j \in [N] \setminus S_k$ such that $f(j) \in f(S_k)$. Use the quantum search procedure which succeeds with probability at least $1/2$ provided S_k contains one element of a collision pair. In case of success, output the collision pair.

THEOREM 3.1. *If f has a collision pair i, j , then the previous algorithm finds it after an expected number of $O(N^{3/4})$ queries to f .*

Proof. With probability at least $1/\sqrt{N}$, step 2(a) selects a subset containing i or j . Suppose this is the case. Then either the set contains a collision pair or it does not. If it does, then step 2(b) finds it, and if it does not, then with probability at least $1/2$, step 2(c) finds a collision pair. Therefore amplitude amplification will iterate the inner loop $O(N^{1/4})$ expected times until it succeeds. Steps 2(b) and 2(c) each use $O(\sqrt{N})$ queries, from which we conclude the claimed complexity. \square

A weaker model is the comparison model, where we are allowed to ask query $f(i) \leq f(j)$ only for given indices i, j , rather than for the actual values $f(i), f(j)$. The previous algorithm can be adapted to that model with the price of an $O(\log N)$ factor in steps 2(b) and 2(c). In contrast, for classical (exact or bounded-error) algorithms, element distinctness is as hard as sorting and requires $\Theta(N \log N)$ comparisons.

4. List intersection. We are given two monotone increasing functions $f, g : [N] \rightarrow [M]$ and search for $i, j \in [N]$ such that $f(i) = g(j)$. A simple algorithm would be to make a quantum search for $i \in [N]$ such that there exists $j \in [N]$ with $f(i) = g(j)$. The quantum search of i will need $O(\sqrt{N})$ iterations, and the binary search of j will need $O(\log N)$ queries. This gives a bounded-error quantum algorithm using $O(\sqrt{N} \log N)$ queries. We now show how to get rid of most of the log factor by exploiting the fact that both functions are monotone increasing.

Our quantum algorithm solves the problem using $O(\sqrt{N} c^{\log^*(N)})$ comparisons for some constant $c > 0$. We define a set of subproblems such that the original problem

(f, g) contains a collision pair if and only if at least one of the subproblems contains one. We then solve the original problem by running the subproblems in quantum parallel and applying amplitude amplification.

Let $1 \leq r < N$ be an integer. For the purpose of defining subproblems we extend the functions f and g to the domain $[1, N+r]$, mapping $f(N+i) = \max\{f(N), g(N)\} + i$ and $g(N+i) = f(N+i) + r$ for all $1 \leq i \leq r$ and extending at the same time the range of f and g to $[M+2r]$. We also define the *insertion point* of some integer $x < h(N+1)$ in a monotone increasing function $h : [N+r] \rightarrow [M+2r]$ as the smallest index i such that $h(i) \geq x$.

We define $2 \lceil \frac{N}{r} \rceil$ subproblems as follows. For each $0 \leq i \leq \lceil N/r \rceil - 1$, consider the subproblem (f_i, g'_i) , where f_i denotes the restriction of f to subdomain $[ir+1, (i+1)r]$ and g'_i denotes the restriction of g to $[j, j+r-1]$, where j is the insertion point of $f(ir+1)$ in g .

Similarly, for each $0 \leq j \leq \lceil N/r \rceil - 1$, consider the subproblem (f'_j, g_j) , where g_j denotes the restriction of g to $[jr+1, (j+1)r]$ and f'_j denotes the restriction of f to $[i, i+r-1]$, where i is the insertion point of $g(jr+1)$ in f .

LEMMA 4.1. *If $i, j \in [N]$ is a collision pair for (f, g) , then it is also a collision pair for one of the subproblems.*

Proof. Let $k = \lfloor i/r \rfloor + 1$ and let k' be the insertion point of $f(k)$ in g . If $j \in [k', k' + r - 1]$, then (i, j) is also a collision pair for the subproblem (f_k, g'_k) . However, if $j \notin [k', k' + r - 1]$, then let $\ell = \lfloor j/r \rfloor + 1$. We have $f(k) \leq g(\ell) \leq f(i)$. Therefore the insertion point ℓ' of $g(\ell)$ in f satisfies $i \in [\ell', \ell' + r - 1]$, from which we conclude that (i, j) is a collision pair for the subproblem (f'_{ℓ}, g_{ℓ}) . \square

THEOREM 4.2. *There exists a quantum algorithm that outputs a collision pair between f and g with probability at least $\frac{2}{3}$ provided one exists, using $O(\sqrt{N} c^{\log^*(N)})$ queries, for some constant $c > 1$.*

Proof. Let $T(N)$ denote the worst-case number of queries required if f and g have domain of size N . We show that

$$(4.1) \quad T(N) \leq c' \sqrt{\frac{N}{r}} (\lceil \log(N+1) \rceil + T(r))$$

for some (small) constant c' . Let $0 \leq i \leq \lceil N/r \rceil - 1$ and consider the subproblem (f_i, g'_i) . To find the insertion point of $f(\lfloor i/r \rfloor + 1)$ in g we need $\lceil \log(N+1) \rceil$ queries by using binary search. Then we need at most $T(r)$ additional queries to find a collision pair for (f_i, g'_i) . There are $2 \lceil \frac{N}{r} \rceil$ subproblems, so by applying amplitude amplification we can find a collision pair among any one of them with probability at least $\frac{2}{3}$, provided there is one, using the number of queries claimed in (4.1).

We pick $r = \lceil \log^2(N) \rceil$. Since $T(r) \geq \Omega(\sqrt{r}) = \Omega(\log N)$, (4.1) implies

$$(4.2) \quad T(N) \leq c'' \sqrt{\frac{N}{r}} T(r)$$

for some constant c'' . Furthermore, our choice of r implies that the depth of the recursion defined by (4.2) is on the order of $\log^*(N)$, so unfolding the recursion gives the theorem. \square

5. Triangle finding. Finally we consider a related search problem. Consider an undirected graph $G = (V, E)$ on $|V| = n$ nodes with $|E| = m$ edges. There are $N = \binom{n}{2}$ edge slots in E , which we can query in a black box fashion (see also [10, section 7]). The goal is now to find distinct vertices $a, b, c \in V$ such that $(a, b), (a, c),$

$(b, c) \in E$. Since there are $\binom{n}{3}$ triples a, b, c , and we can decide whether a given triple is a triangle using three queries, we can use Grover's algorithm to find a triangle in $O(n^{3/2})$ queries. Below we give an algorithm that has the same complexity for dense graphs $m = O(n^2)$ but is more efficient for sparse graphs. In particular when $m = O(n)$, then the algorithm uses only $O(n)$ queries, while any classical bounded-error algorithm needs $\Omega(n^2)$ queries by a sensitivity argument for distinguishing the star graph, with the same graph augmented by a single edge.

ALGORITHM: FIND A TRIANGLE

1. Use the bounded-error quantum counting procedure from [7, Theorem 18] to get a factor-2 estimation m' of the number of edges m , with $O(n)$ expected queries.
2. Apply amplitude amplification to the following *inner block*, interrupting it after $O(\sqrt{m'})$ calls to the inner block.
 - (a) Use quantum search to find an edge $(a, b) \in E$ among all $\binom{n}{2}$ potential edges, using at most $O(n/\sqrt{m'})$ queries.
 - (b) Use quantum search to find a node $c \in V$ such that a, b, c is a triangle, using at most (n) queries.
3. Repeat until a triangle is found.

Quantum search of an edge $(a, b) \in E$ succeeds after $O(n/\sqrt{m})$ expected queries. Since amplitude amplification forbids any observation in the inner block, we need step 2 to get an estimation of m , which determines the number of queries after which step 2(a) will be interrupted.

THEOREM 5.1. *If the graph contains a triangle, then the previous algorithm finds one after $O(n + \sqrt{nm})$ expected queries.*

Proof. Suppose the graph contains a triangle. Let an edge be *good* if it is part of a triangle. Then step 2(a) finds one with probability at least $1/2m$. Given this event, step 2(b) finds a triangle with probability at least $1/2$. Now suppose that step 1 found the correct estimation of m . Therefore due to the amplitude amplification step 2 succeeds with probability at least $1/2$.

Finally the expected number of repetitions generated by step 3 is constant.

Each iteration costs $O(n + \sqrt{nm'})$ queries, where m' is the random outcome of step 2 with expectation m . This establishes the claimed complexity. \square

6. Concluding remarks. An interesting related problem that is still wide open is the issue of *time-space tradeoffs* for element distinctness. Such tradeoffs have been studied for classical algorithms by Yao [24], Ajtai [2], Beame, Saks, Sun, and Vee [5], and others. In particular, Yao shows that the time-space product of any classical deterministic comparison-based branching program solving element distinctness satisfies $TS \geq \Omega(N^{2-\varepsilon(N)})$, where $\varepsilon(N) = 5/\sqrt{\ln N}$. An upper bound $TS = O((N \log N)^2)$ is achievable classically.

Ignoring logarithmic factors, the quantum algorithm presented here uses time $T = N^{3/4}$ and space $S = N^{1/2}$. An alternative quantum algorithm is to search the space of all $\binom{N}{2}$ (x, y) -pairs to try to find a collision. This algorithm has roughly $T = N$ and $S = \log N$. Third, Ambainis's new algorithm has $T = N^{2/3}$ and $S = N^{2/3}$. All these algorithms satisfy $T^2S \approx N^2$. In fact, for every space bound S less than $N^{2/3}$, one can find an algorithm whose time (or query) complexity T satisfies $T^2S \approx N^2$. We conjecture that this is close to optimal. Proving this would be very interesting, since no nontrivial quantum time-space tradeoff lower bounds are known for any decision problem (some tradeoffs for multiple-output problems may be found in [17]).
